Introduction

A popular saying is “Learn to walk before you run”. We could expand this to “Learn to crawl before you learn to walk before you learn to run before you learn to sprint”. When it comes to regression analysis we have to admit that this column has spent rather more time on Partial Least Squares (PLS) than on Principal Component Analysis Regression (PCR) than on Multiple Linear Regression (MLR) and none on Classical Least Squares (CLS). This can be viewed as the opposite of the accepted wisdom of doing the easiest things first! This edition of the column is a partial redress of the admitted bias but also an explanation of why CLS is not often used in spectroscopy.

Some years ago an attempt was made to show the relationships of the first three of these methods which more recent followers of the column might like to read. The advantages and limitations of each method are summarised in Table 1.

There have been some recent developments in the CLS method which may make it more applicable to spectroscopic data so you may see references and wonder why we had not mentioned it.

Classical least squares

The basic idea is that if you have the spectrum of a mixture and the spectra of all the components, then you can compute the composition of the mixture. For this to work there are some important requirements: the system must be linear and additive (no interactions between the components), the component spectra must be linearly independent and, for a perfect recovery of the composition, the system must be free of noise.

The theory in pictures

Figure 1 shows the “spectra” of three components, each one with a single Gaussian peak, and the spectrum of a mixture of the three in the proportions (0.5, 0.4, 0.1). All the spectra were created mathematically. The mixture spectrum in (d) was obtained by multiplying the spectra in (a), (b) and (c) by 0.5, 0.4 and 0.1, respectively, and adding the results. If we have all these four spectra, and we may assume that (d) was generated as a mixture in exactly this way but with unknown mixing proportions, then it is possible to recover the proportions from the four spectra. Under some fairly mild conditions on the component spectra, there is one and only one set of proportions that could have given the spectrum in (d).

The mathematics

If we write the four spectra as column vectors of length \( q = 100 \), with \( s_1 \), \( s_2 \) and \( s_3 \) being the pure spectra and \( x \) the mixture spectrum, then the mixing corresponds to

\[
\mathbf{x} = c_1 \mathbf{s}_1 + c_2 \mathbf{s}_2 + c_3 \mathbf{s}_3
\]

(1)

where the scalars \( c_1 \), \( c_2 \) and \( c_3 \) are the proportions of components 1, 2 and 3 in the mixture.

Equation 1 has a matrix version. [Readers who are not conversant with matrix algebra might like to read our mini series on matrix algebra in earlier TD columns which are available on]

Table 1. Properties of different methods of regression analysis.

<table>
<thead>
<tr>
<th>Method</th>
<th>Principle</th>
<th>Advantages</th>
<th>Disadvantages</th>
</tr>
</thead>
<tbody>
<tr>
<td>CLS</td>
<td>Addition of component spectra</td>
<td>Intuitive</td>
<td>Restricted by requirements</td>
</tr>
<tr>
<td>MLR</td>
<td>Selection of a few measured variables to form a predictive equation</td>
<td>Easily comprehensible; very robust when applied to a few variables</td>
<td>Easily over-fitted when using a large number of variables and not many samples</td>
</tr>
<tr>
<td>PCR</td>
<td>Computation of principal components (sources of variability in the data) followed by MLR on the PCs</td>
<td>Statistically sound, well researched; PCs can often be recognised; good results</td>
<td>More complex to understand, limited availability of good software</td>
</tr>
<tr>
<td>PLS</td>
<td>Computation of new variables as a compromise between MLR and PCR to form a predictive equation</td>
<td>May give better results than PCR; excellent software available</td>
<td>More complex than PCR to understand; requires careful validation</td>
</tr>
</tbody>
</table>
If the system behaves as assumed, and there is no noise anywhere, Equation (3) recovers the exact proportions in the mixture. This is a calculation, not an estimation. Alas, real systems have noise. Suppose we assume additive independent noise, so that Equation (1) becomes

$$x = Sc + e$$

This is the familiar linear model, with $c$ playing the role of parameter vector, and Equation (3) is the equally familiar least squares estimate of $c$. Thus the formula does not change when we have a noisy system, but the result is now an estimate of the proportions in the mixture and not an exact calculation.
How good an estimate it is will depend on the amount of noise, and also on how distinct are the three pure spectra. The overlap between the peaks in (a) and (b) did not matter when there was no noise, but when there is noise this overlap will degrade the quality of the estimates to some extent. What happens when there is noise this overlap will degrade the quality of the estimates to some extent. What happens when working in reflectance mode, scatter effects are also a problem since the introduction of arbitrary multiplicative factors into all the spectra rather spoils the maths.

For all these reasons, this approach in its simple form as presented above is not often useful for spectroscopy. So when colleagues ask you "Why don't you use CLS?" you now know the answer! However, it can provide a starting point for more sophisticated approaches that may be useful in the future.

Reading more
There is a very detailed description of CLS, with two worked examples, in the chemometrics book by Beebe, Pell and Seasholtz. It is also explained there how the method can easily be extended to cope with variable linear baselines. The paper by Mark et al. discusses the units for the concentrations that the mixture proportions represent (weight fraction? volume fraction? ...), something that is not important for the mathematics but is important in a real example and this needs to be taken seriously if you think that you have an example that fulfils the requirements.
